## Bearing Type Selection

Bearing type selection is made after the general design concept of the machine has been established and the magnitude of the loads and speeds estimated. Special conditions can directly affect bearing operation and must be considered. These include ambient or localized temperatures, shock or vibration, type of lubrication, dirt or abrasive contamination, difficulty in obtaining accurate alignment, space limitations, need for shaft rigidity, etc.

The fields of application for many types of bearings overlap, and the value of experience in bearing applications cannot be overemphasized.

Torrington's Sales and Engineering personnel have a wealth of experience in the design and application of rolling element bearings. Their knowledge can help solve your bearing application problems. All new applications of Torrington Bearings should be submitted to Torrington for approval.

These engineering services are rendered confidentially, and we urge you to use them since such procedure assures selection of the proper bearing in terms of maximum service and economy.

Each type of bearing has inherent features which determine its relative suitability for a specific application. Careful analysis of the features, and familiarization with the fundamental characteristics of each type of bearing, will help in selecting the proper bearing. The right is reserved to change design and specifications without notice.

The following information will provide guidance in your initial selection of the proper radial bearing. Thrust bearing type selection is discussed in the Thrust Bearing section.

## FULL COMPLEMENT VERSUS CAGED NEEDLE ROLLER BEARINGS

Load rating - size for size, full complement bearings have more rollers. With more rollers contacting the raceway in the load zone, they generally have higher load ratings than caged bearings. This is particularly important under static, slow rotating, or oscillating conditions. Both types, however, have far greater capacity in less radial space than other types of rolling element bearings.

Slope Tolerance - Controlled Contour Rollers and the guidance of rollers supplied by the cage make the caged bearings preferable to the full complement bearing in applications where misalignment or shaft deflection is a factor.

Speed - for moderate speeds, both types are satisfactory. The caged bearing, however, permits higher speeds for a given shaft size.

Pregreased life - the expression refers to the maintenance-free life of a prelubricated bearing. It is significantly longer for a caged bearing because: (1) of its greater grease storage capacity, and (2) with less internal friction, it runs cooler.

Coefficient of friction - generally, the power loss in a rolling element bearing is so slight it can be ignored. Occasionally, the coefficient of friction must be known. The coefficient depends on many variables, such as speed, magnitude of load and lubricant viscosity and flow rate.

In a caged bearing, the frictional loss is less than in a full complement bearing because the cage improves roller guidance and reduces rubbing velocities by eliminating roller-to-roller contact.

No accurate method exists for predicting the coefficient of friction of a specific bearing under all conditions of operation. Approximate values for bearing friction under normal loads with oil lubrication have been established by test. From such tests, the coefficients of friction for radial bearings are:

$$
\begin{aligned}
\text { caged needle roller bearings } & =15 \cdot 10^{-4} \\
\text { full complement needle roller bearings } & =25 \cdot 10^{-4}
\end{aligned}
$$

where the following formula defines the coefficient of friction:

$$
\begin{gathered}
\text { coefficient } \\
\text { of friction }
\end{gathered}=\frac{\text { torque to turn bearing }}{\text { load on bearing } \cdot \text { bearing pitch radius }}
$$

Cost - because of their lower cost, the various types of Drawn Cup bearings should be considered first for any application.

## DRAWN CUP BEARINGS WITH DEEPLY HARDENED AND GROUND RACEWAYS

Load rating - the drawn cup bearing has an outer ring with a necessarily thin hardened case over a relatively ductile core. A bearing with a machined, deeply hardened and ground raceway therefore shows slightly higher load ratings than a drawn cup bearing of similar size and similar roller guidance method. However, a bearing with a deeply hardened ring, as compared with a drawn cup bearing, has more advantages when the applied loads are extremely heavy, beyond the strength of the case and core of the drawn cup bearing.

Cross section - a smaller, more compact cross section is provided by the drawn cup bearing, with its smaller roller diameter and thin steel outer ring, contrasted with the larger roller diameter and thicker outer ring of the heavy duty bearing.

Only caged needle roller assemblies and complements of loose needle rollers are more compact than drawn cup bearings, but they require the use of hardened outer and inner raceways.

Cost - because of their lower cost, the various types of Drawn Cup bearings should be considered first for any application which needs an integral hardened outer raceway.

Split housings - the heavy duty bearing, with a relatively thick and rigid outer ring, can be used in a split housing. The drawn cup bearing, because of its thin, drawn outer ring construction, depends on the strength and roundness of the housing to achieve its final bearing roundness and operational clearances.

Therefore, while it is possible to use a split housing with a heavy duty bearing, it is recommended that the drawn cup bearing be first installed in a steel sleeve to round and size the bearing before assembly in the split housing.

Mounting - heavy duty bearings should be located axially in the housing by shoulders or other devices. Drawn cup bearings offer attractive manufacturing economies, because they are pressed into through-bored housings and do not require any other means for axial location.

## Bearing Size Selection

From the foregoing discussion of the operating characteristics of the full complement and caged needle roller bearings listed in this catalog, the designer can determine the type of bearing most suitable for the specific conditions of an application. In many cases, more than one bearing type will meet the operating criteria. In these instances, the designer should select the most suitable size of each type and then make a final selection on the basis of mounting simplicity, available space and over-all economy. Needle roller bearings tabulated in this catalog meet tolerances specified for them in the respective ANSI/ABMA and ISO standards.

The basic parameters of bearing size selection are radial load, thrust load, speed, required life, and raceway hardness conditions. Other factors, such as misalignment, abnormal temperature, contamination and poor lubrication, can seriously reduce service life, but their effect is not easily determined. Instead of attempting to estimate their effect on bearing life, every attempt should be made to eliminate these conditions through proper design.

## BEARING LIFE AND RELIABILITY

The life of a bearing is expressed as the number of revolutions (or the number of hours at a given speed) that a bearing will complete before failure. Life will vary from one bearing to another, but stabilizes into a predictable pattern when considering a large group of the same size and type bearing. The " $\mathrm{L}_{10}$ " or "rating life" of a group of such bearings is defined as the number of revolutions (or hours at a given constant speed) that $90 \%$ of the tested bearings will complete or exceed before the first evidence of failure develops. Thus it can be predicted with $90 \%$ reliability that a bearing will meet or exceed the calculated " $\mathrm{L}_{10}$ " life providing normal fatigue is the failure mode.

Some critical applications, however, require definition of life at reliabilities greater than $90 \%$. To determine bearing life with reliabilities greater than $90 \%$, the " $L_{10}$ " life as calculated must be adjusted by a factor $a_{1}$ so that $L_{n}=a_{1} L_{10}$. The life adjustment factors shown in Table 1 are recommended.

Table 1 - Life Adjustment Factors

| Reliability \% | $\mathbf{L}_{\boldsymbol{n}}$ <br> Rating Life | $\mathbf{a}_{\mathbf{1}}$ <br> Life Adjustment <br> Reliability Factor |
| :---: | :---: | :---: |
| 90 | $\mathrm{~L}_{10}$ | 1 |
| 95 | $\mathrm{~L}_{5}$ | 0.62 |
| 96 | $\mathrm{~L}_{4}$ | 0.53 |
| 97 | $\mathrm{~L}_{3}$ | 0.44 |
| 98 | $\mathrm{~L}_{2}$ | 0.33 |
| 99 | $\mathrm{~L}_{1}$ | 0.21 |

In some applications, when safety or maintenance economy is not critical and low initial bearing cost is the prime consideration, the reliability level can be reduced to $50 \%$, or the " $L_{50}$ " life. The " $L_{50}$ " life may be as much as five times the " $\mathrm{L}_{10}$ " rating life.

## DEFINITION OF LOAD RATINGS

Basic dynamic load rating - The "basic dynamic load rating" ( $\mathrm{C}_{\mathrm{r}}$ ) for a radial roller bearing is that calculated, constant, radial load, which a group of apparently identical bearings with stationary outer ring can theoretically endure for a rating life of one million revolutions of the inner ring. For a thrust roller bearing $\left(\mathrm{C}_{\mathrm{a}}\right)$ is that calculated, constant, centric thrust load, which a group of apparently identical bearings can theoretically endure for a rating life of one million revolutions of the bearing washers. The basic dynamic load rating is a reference value only, the base value of one million revolutions has been chosen for ease of calculation. Since applied loading as great as the basic dynamic load tends to cause local plastic deformation of the rolling surfaces, it is not anticipated that such heavy loading would normally be applied.

The dynamic load ratings tabulated in this catalog are based on extensive test and field experience. Torrington dynamic load ratings are not necessarily the same as those calculated using the recommendations of ISO and other standard institutes. Use of the Torrington load ratings results in the selection of bearings, which perform in actual service as predicted by this catalog as long as satisfactory conditions of lubrication, cleanliness, alignment, etc., are maintained. Torrington load ratings are denoted by the column heading $\mathbb{T}$. ISO 281 ratings are tabulated for comparison purposes only.

Basic static load rating - for a radial roller bearing suitably manufactured from a good quality hardened alloy steel, the static radial load $\mathrm{C}_{0} r$ is that uniformly distributed static radial bearing load, which produces a maximum contact stress of 4000 megapascals ( $580,000 \mathrm{PSI}$ ) acting at the center of contact of the most heavily loaded rolling element. The static axial load rating $\left(\mathrm{C}_{\mathrm{oa}}\right)$ is that uniformly distributed static centric axial bearing load, which produces a maximum contact stress of 4000 megapascals ( $580,000 \mathrm{PSI}$ ) acting at the center of contact of the each rolling element.
Note: For a contact stress of 4000 MPa , a total permanent deformation of roller and raceway occurs, which is approximately 0.0001 of the roller diameter.

Dynamic working load - For most industrial applications, the maximum dynamic working load should not exceed the basic dynamic load rating (T) or the tabulated working load whichever is smaller.

Load ratings for bearings used in airframes - Airframe designers commonly use the terms "limit load" rating and "ultimate" or "static fracture load" rating.

Limit load rating - (the working load for airframe bearings) can be defined as the maximum radial load which can be applied to a bearing without impairing the subsequent functioning of the bearing in airframe applications.

Ultimate or static fracture load rating is not less than 1.5 times the limit load rating.

Aircraft static capacity, where listed, is based on the rolling elements of the bearing only. For properly housed bearings, the aircraft static capacity corresponds to the ultimate or static fracture load rating.

For capacities of airframe bearings operating as track rollers and for capacities of tracks on which the bearings roll please refer to the airframe bearings section of this catalog.

## Bearing Size Selection (continued)

## LIFE AND LOAD RELATIONSHIP

Empirical calculations and experimental data point to a predictable relationship between bearing load and life. This relationship may be expressed by a formula. In this empirical formula, the bearing life is found to vary inversely as the applied load to an exponential power. The assigned value of the exponent depends on the basic type of rolling element. For all types of Torrington needle roller bearings the formula is:
life
(millions of revolutions)
$=\left(\frac{\text { basic dynamic load rating }}{\text { applied load }}\right)^{10 / 3}$
Consequently, if the load applied to a given bearing is increased by a factor of 2 the life is decreased by a factor of 10 .

Since bearing life in revolutions equals rpm $\cdot 60$ • life in hours, an increase in speed results in a decrease in hours of life as long as other factors are the same. For example, if the speed is doubled, the hours of life are halved. Conversely, if the speed is halved the hours of life are doubled.

When the applied load is greater than one-half of the basic dynamic load rating, the above load-life relationship is no longer valid. Consult the Torrington engineering department for recommendations.

Table 2- Working Load Factors (Static)

## EFFECT OF RACEWAY HARDNESS

Both the dynamic and static load ratings of bearings in this catalog are based on a minimum raceway hardness equivalent to 58 HRC (ref.ASTM, E-18). If the raceway hardness must be decreased, then these load ratings must be reduced.

When the loading is static, it is usually recommended that the static load rating (or limit load rating for airframe bearings) divided bythe appropriate factor as shown in Table 2.

The raceway hardness also affects the life of the bearing application even though the applied load is less than the maximum recommended working load discussed above. Table 3 shows the Hardness Factors (HF) by which the basic dynamic load rating should be divided where the raceway hardness must be less than 58 HRC or equivalent.

Table 3 - Hardness Factors to Modify Basic Dynamic Load Rating

| Raceway <br> Hardness <br> HRC | Hardness <br> Factor <br> HF |
| :---: | :---: |
| 58 | 1.00 |

| 40 | 4.55 |

## Bearing Life Calculations

To calculate $L_{10}$ life for a selected bearing under given conditions of speed, load and raceway hardness, use the general formula:

$$
\mathrm{LF}=\frac{\mathrm{C}_{\mathrm{r}}\left(\text { or } \mathrm{C}_{\mathrm{a}}\right)}{\mathrm{SF} \cdot \mathrm{P} \cdot \mathrm{HF}}
$$

to obtain the Life Factor (LF). Then simply read off the hours of $L_{10}$ life from the Life Chart shown at the right (and on tabular pages). In this formula:
$C_{r}=$ Basic dynamic load rating as found on the tabular pages $\left(C_{a}\right.$ for thrust bearings $)$.
SF = Speed Factor, obtained from speed chart shown at right (and on tabular pages).
$\mathrm{P}=$ Applied Load
HF = Hardness Factor (See Table 3)
In those instances where calculating the required basic dynamic load rating facilitates the choice of a bearing, use the same formula restated as follows:

Required $\mathrm{C}_{\mathrm{r}}\left(\right.$ or $\left.\mathrm{C}_{\mathrm{a}}\right)=\mathrm{P} \cdot \mathrm{SF} \cdot \mathrm{LF} \cdot \mathrm{HF}$
Similarly, the load a bearing will support under various conditions of speed and life can be calculated from this restatement of the basic formula:

$$
\text { allowable load at given conditions }=\frac{\mathrm{C}_{\mathrm{r}}\left(\operatorname{or} \mathrm{C}_{\mathrm{a}}\right)}{\mathrm{SF} \cdot \mathrm{LF} \cdot \mathrm{HF}}
$$

The equations above are based on ideal conditions, and if excessive vibration, lubrication problems, shock loading, extreme temperatures, unusual misalignment, or any other abnormal conditions are present, consult Torrington for recommendations. In oscillating applications, especially those of very small amplitudes, fretting corrosion can be a problem requiring consultation.

Consult our Bearing Engineering Department before final bearing selection is made.

Example: A review of operating conditions and other factors (see Bearing type Selection) leads to the selection of a full complement drawn cup needle roller bearing. The available space accommodates the $B-1212$ bearing. Find the $L_{10}$ life under the following conditions:
Speed $(\mathrm{rpm})=$

$$
700(\mathrm{SF}=2.5)
$$

- 

Applied radial load $(P)=490 \mathrm{lbf}{ }^{*} \quad$ *See note below.
Shaft raceway hardness $=50$ HRC

$$
(\mathrm{HF}=1.59)
$$

Working Load (max.) $=4710$ lbf
Basic dynamic load rating $\left(C_{r}\right)=3160 \mathrm{lbf}$

* Applied load of 490 lbf is satisfactory since it is less than the basic dynamic load rating $\mathrm{C}_{\mathrm{r}}$.

$$
\mathrm{LF}=\frac{3160}{2.50 \cdot 490 \cdot 1.59}=1.63
$$

From nomograph $L_{10}=2530$ hours
Example: Find the required basic dynamic load rating $\left(\mathrm{C}_{\mathrm{r}}\right)$ for a bearing which will carry an applied radial load $(P)$ of 260 lbf for 4000 hours minimum life $\left(L_{10}\right)$ at 2000 rpm and raceway hardness of 58 HRC:
Applied radial load $(P)=260 \mathrm{lbf}$ Speed $=2000$ rpm (SF = 3.41) Minimum life $\left(\mathrm{L}_{10}\right)=4000$ hrs. $(\mathrm{LF}=1.87)$ Raceway hardness $=58 \mathrm{HRC}(\mathrm{HF}=1.00)$ $\mathrm{C}_{\mathrm{r}}=260 \cdot 3.41 \cdot 1.87 \cdot 1.00=1658 \mathrm{lbf}$
${ }^{*}$ Note: When using the required $C_{r}$ to select a type DC bearing, be sure to match it against values in the $(T)$ column of the tables of dimensions and capacities.
Thus, the $\mathrm{J}-1212$ with $\mathrm{C}_{\mathrm{r}}=2320$ lbf might be chosen.
The applied load is well below the allowable working load of the $\mathrm{J}-1212$ which, on the shaft raceway of 58 HRC hardness, is the $\mathrm{C}_{\mathrm{r}}$ value of 2320 lbf .

## speed

rpm factor

.

## Bearing Life Calculations (continued)

## BEARING LIFE UNDER VARIABLE LOADS AND SPEEDS, EQUIVALENT LOAD

When a bearing is subjected to varying loads and speeds the equivalent (constant) load ( $\mathrm{P}_{\mathrm{e}}$ ) on the bearing can be determined using the following formula:
$P_{e}=\sqrt[10 / 3]{\frac{\left(F_{1}\right)^{10 / 3} \mathrm{pm}_{1} \cdot t_{1}+\left(F_{2}\right)^{10 / 3} \cdot \mathrm{rpm}_{2} \cdot \mathrm{t}_{2}+\ldots\left(\mathrm{F}_{\mathrm{n}}\right)^{10 / 3} \mathrm{rpm}_{\mathrm{n}} \cdot \mathrm{t}_{\mathrm{n}}}{N}}$
where $F_{1}, F_{2}, \ldots F_{n}$ represent loads acting at speeds $\mathrm{rpm1} 1, \mathrm{rpm}_{2}, \ldots$ $\mathrm{rpm}_{\mathrm{n}}$ and $\mathrm{t}_{1}, \mathrm{t}_{2} \ldots \mathrm{t}_{\mathrm{n}}$ represent the decimal portion of the total time that $F_{1}$ is acting at $r p m_{1}, F_{2}$ is acting at $r p m_{2} \ldots F_{n}$ is acting at $r p m_{n}$. The weighted rpm, $N$, is the numerical summation of $\mathrm{t}_{1} \mathrm{rpm}_{1}$ plus $\mathrm{t}_{2} \mathrm{rpm}_{2}$ plus.... $\mathrm{t}_{\mathrm{n}} \mathrm{rpm} \mathrm{m}_{\mathrm{n}}$.

## BEARING LIFE FOR GIVEN LOAD AND SPEED

When a bearing must be selected to meet given load and speed conditions, the following formula is used to compute the required basic dynamic load rating:
$\mathrm{C}_{\mathrm{r}}\left(\right.$ or $\left.\mathrm{C}_{\mathrm{a}}\right)=\mathrm{P}_{\mathrm{e}} \cdot \mathrm{LF} \cdot \mathrm{SF}$
where $\mathrm{C}_{\mathrm{r}}\left(\right.$ or $\left.\mathrm{C}_{\mathrm{a}}\right)=$ basic dynamic load rating
$\mathrm{LF}=$ life factor for the total hours the bearing must operate
$\mathrm{SF}=$ speed factor for weighted rpm (N)
$P_{e}=$ equivalent load
If, however, the bearing to be used has already been selected, the following formula is used to determine whether the total desired hours can be achieved:

$$
\mathrm{LF}=\frac{\mathrm{C}_{\mathrm{r}}\left(\text { or } \mathrm{C}_{\mathrm{a}}\right)}{\mathrm{P}_{\mathrm{a}} \cdot \mathrm{Sf}}
$$

## Additional Factors Affecting Bearing Operation

## Lubrication

The basic dynamic load ratings listed in this catalog assume the use of mineral or synthetic oils with sufficient lubricity and a minimum viscosity of 100 Saybolt Universal Seconds (S.U.S.) or 20 centistokes (cSt) at the bearing operating temperature. If the viscosity is less than this, or the oils lack lubricity, the life of the bearing may be reduced.
Since the lubricant affects bearing life and operation, selecting the proper lubricant is an important design function. The purpose of lubrication in bearing application is :
(1) to minimize friction at points of contact within the bearings
(2) to protect the highly finished bearing surfaces from corrosion
(3) to dissipate heat generated within the bearings
(4) to remove or prevent entry of foreign matter.

Either oil or grease may be used with rolling element bearings. Each has its advantages and limitations.

Since oil is a liquid, it lubricates all surfaces and dissipates heat from these surfaces more readily. It is generally used for high speed applications. Oil lubricants can be circulated, cleaned and cooled for more effective lubrication.

Grease, which is easier to retain in the bearing housing, aids as a sealant against foreign matter.

However, the grease must also be compounded with mineral or synthetic oils whose viscosity is greater than 100 S.U.S. or 20 centistokes at the operating temperature and have good lubricity.

Frequent replenishing of the grease may be necessary for optimum performance.

Some bearing types in this catalog are prepacked with a grease suitable for their normal application. For instance, airframe bearings are supplied prepacked with a special wide temperature range aircraft grease. The stud and yoke type track rollers are prepacked with a medium temperature grease.

The remainder of the bearings are normally shipped protected with corrosion-preventative compound which is not a lubricant. Such bearings may be used in oil lubricated applications without removal of the corrosion preventative compound. The packing label indicates the type of lubricant or corrosion preventative compound within the bearing.

When specified by the customer, other Torrington bearings may be ordered prelubricated with suitable greases and oils. Care must be exercised in lubricant selection since different lubricants are often incompatible.

## LIMITING SPEEDS

Since load, lubrication method, temperature and other factors affect the maximum speeds at which bearings will operate, it is impossible to determine precise limiting speeds. Th elimiting speeds listed in this catalog can readily be reached by moderately loaded bearings using normal splash or drip feed mineral oils. Heavy loads or oils of less lubricity may require increased lubricant flow rate to dissipate heat at high bearing speed.

With carefully controlled geometry and improved lubrication provisions, the limiting speeds may be exceeded.

Grease lubricated bearings can reach the listed limiting speeds as long as the loads are light and the frictional heat can be readily dissipated through the shaft and housing.

Only testing will determine the ultimate speed which can be reached in a specific application.

## MISALIGNMENT AND OPERATING DEFLECTION

The effect of misalignment on operating deflection may result in the shaft raceway or inner ring having a slope relative to the centerline of the path of rollers in the bearing. Such slope causes an unequal distribution of contact stress along the length of the rollers and a subsequent reduction in bearing life.

The load ratings in this catalog are sufficiently conservative so that if the slope values in Table 4 are not exceeded, the calculated bearing life should be achieved.

With reasonable attention to design, deflection of the housing and shaft can be balanced so that in most applications the slopes tabulated need not be exceeded. If such design cannot be achieved, bearing function will be adversely affected.

Table 4 - Slope Values

| Bearing Width | Maximum Slope |  |
| :--- | ---: | :---: |
|  | Caged | Full Complement |
| $>2$ in. or 50 mm | $5 \cdot 10^{-4}$ | $5 \cdot 10^{-4}$ |
| $1-2$ in. or $25-50 \mathrm{~mm}$ | $10 \cdot 10^{-4}$ | $5 \cdot 10^{-4}$ |
| $<1$ in. or 25 mm | $15 \cdot 10^{-4}$ | $10 \cdot 10^{-4}$ |

7. end chamfer - for most effective assembly of the shaft into a bearing, the end of the shaft should have a large chamfer or rounding. This should help in preventing damage to the roller complement, scratching of the raceway surface and nicking of the shaft end.
8. sealing surface - in some instances bearings have integral or immediately adjacent seals that operate on the surface ground for the bearing raceway. Here, particular attention should be paid to the pattern of the shaft finish. In no instance should there be a "lead", or spiral effect, as often occurs with through feed centerless grinding. Such a "lead" may pump lubricant past the seal.

When it is undesirable or impractical to prepare the shaft to be used as a raceway, inner rings are available as listed in the tabular pages. If the shaft is not used directly as a raceway, the following design specifications must be met:

1. strength - the shaft must be of sufficient size to keep the operating deflections within the limits outlined in Table 4.
2. tolerance - the recommended shaft diameter tolerances for mounting inner rings are indicated on the tabular pages.
3. taper and out-of-roundness - the taper and out-of-roundness should not exceed one-half the shaft diameter tolerance.
4. surface finish - the surface finish should not exceed 125 microinches, aa (arithmetic average) or $3.2 \mu \mathrm{~m}$ (on the Ra scale).
5. locating shoulders or steps - locating shoulders or steps in the shaft must be held to close concentricity with the bearing seat to prevent imbalance and resultant vibrations.

## Housing Design

## BEARINGS WITH OUTER RINGS

For bearings with outer rings the function of the housing is to locate and support the outer ring. The following specifications must be met:

1. strength - housings should be designed so that the radial loads which will be placed on the bearings will cause a minimum of deflection or distortion of the housing.
2. tolerance - the recommended housing bore tolerances for each type of needle roller bearing are indicated on the tabular pages.
3. taper - the taper within the length of the outer ring should not exceed .0005 inch ( 0.013 mm ).
4.out-of-roundness - the housing bore should be round within onehalf the housing bore diameter tolerance.
4. parallelism - when possible, line bore housings which are common to one shaft to obtain parallelism of the housing bores and the shaft axis.
5. surface finish - the surface finish of housing bore should not exceed 125 microinches, aa (arithmetic average) or $3.2 \mu \mathrm{~m}$ (on the Ra scale).
6. end chamfer - to permit easy introduction of the bearing into the housing, the end of the housing should have a generous chamfer.

Heavy duty roller bearings can be installed into housings with a transition fit or a clearance fit. The outer ring should be a transition fit in the housing when it rotates relative with the load. The outer ring may be a clearance fit in the housing when it is stationary relative to the load.In either case, locate the bearings by shoulders, or other locating devises, to prevent axial movement.

Since the heavy duty roller bearing does not require an interference fit in the housing to round and size it properly, a split housing may be used if desired. Dowels should be used to maintain proper register of the housing sections.

Drawn cup bearings have a thin case-hardened outer ring which is out-of-round from the hardening operation. For proper mounting it must always be pressed into the housing. Split housing will not round and size a drawn cup bearing. When split housings must be used, the bearing should first be mounted in a cylindrical sleeve.

The housing should be of sufficient tensile strength and section to round and size the bearing. It must be designed for minimum distortion under load. Steel or cast iron housings are preferred. Housing bores in low tensile strength materials such as aluminum, magnesium, phenolics, etc., should be reduced to provide more interference fit. Thin section cast iron and steel housings may also require reduced bores. Consult the Torrington engineering department for recommendations when working with these lower strength housings.

The housing should be through bored if possible. When shouldered housing bores are unavoidable, the bearing should be located far enough from the shoulder to avoid the danger of crushing the end of the drawn cup during installation.

When the drawn cup bearing is mounted close to the housing face, care should be taken to mount the bearing at least 0.008 inch $(0.20 \mathrm{~mm})$ within the housing face to protect the bearing lip.

## BEARINGS WITHOUT OUTER RINGS

In many cases, such as with gear bores, it is desirable to have the housing bore serve as the outer raceway for caged needle roller assemblies or loose needle roller complements. In those instances, the following specifications must be met:

1. strength - the housing must be of sufficient cross section to maintain proper roundness and running clearance under the maximum load.
2. metallurgical - material selection, hardness and case depth should be consistent with the requirements for inner raceways given in the SHAFT DESIGN recommendations on page E77.
3. taper and out-of-roundness - the raceway out-of-roundness and taper should not exceed 0.0003 inch ( 0.008 mm ) or one-half the bore tolerance, whichever is smaller. In addition, the bore diameter must never be smaller at both ends than in the center (sway-back).
4. surface finish - the raceway surface finish should not exceed 32 microinches, aa (arithmetic average) or $0.8 \mu \mathrm{~m}$ (on the Ra scale). In addition, the surface must be free of nicks, dents and scratches.
5. grind reliefs - care must be exercised to ensure that grind reliefes, fillets, etc. do not extend to the raceway. Oil holes in the raceway area are permissible but the edges must be blended smoothly with the raceway.

## CONTROLLED CONTOUR ROLLERS

Roller bearing life is affected by the distribution of contact stress between roller and raceways. Even when cylindrical rollers are loaded under conditions of ideal alignment, the contact stress is not uniform along the length of the rollers, but rather is concentrated towards the ends. Misalignment causes even greater roller contact stress. This effect is illustrated in Figure 1.

(exaggerated for clarity)

Figure 1: Comparative Stress Patterns
The use of Controlled Contour rollers in certain types and sizes of Torrington Bearings helps to reduce stress concentration at the ends of rollers, both under misalignment or ideal alignment, and results in more uniform stress distribution and optimum bearing performance.
